Review article: Kinematic models of the interplanetary magnetic field

Christoph Lhotka¹ and Yasuhito Narita¹

¹Space Research Institute, Austrian Academy of Sciences, Schmiedlstr. 6, A-8042 Graz, Austria

Abstract. Current knowledge on the description of the interplanetary magnetic field is reviewed with an emphasis on the kinematic approach as well as the analytic expression. Starting with the Parker spiral field approach, further effects are incorporated into this fundamental magnetic field model, including the latitudinal dependence, the northward component, the solar cycle dependence, and the polarity and tilt angle of the solar magnetic axis. Further extensions are discussed in view of the magnetohydrodynamic treatment, the turbulence effect, the pickup ions, and the stellar wind models. The models of the interplanetary magnetic field serve as a useful tool for theoretical studies, in particular on the problems of plasma turbulence evolution, charged dust motions, and cosmic ray modulation in the heliosphere.

1 Introduction

The interplanetary magnetic field (IMF) is a spatially extended magnetic field of the Sun, and forms together with the plasma flow from the Sun (referred to as the solar wind) a spatial domain of the heliosphere¹ around the Sun surrounded by the local interstellar cloud. Starting with the first direct measurements in 1960’s (Ness et al., 1964; Ness and Wilcox, 1964; Wilcox and Ness, 1965; Wilcox, 1968), the IMF is becoming increasingly more accessible in various places in situ in the solar system, e.g., the inner heliosphere (closer than the Earth orbit from the Sun) was covered by the Helios mission (Porsche, 1981), see monograph by Schwenn and Marsch (1990, 1991), the outer heliosphere (beyond the Earth orbit) by Voyager (Stone, 1977; Kohlhase and Penzo, 1977; Stone, 1983), and the high-latitude region by the Ulysses mission (Wenzel and Smith, 1991; Wenzel et al., 1992).

In the lowest-order picture, IMF has an Archimedian spiral structure, also referred to as the Parker spiral after Parker (1958), imposed by the solar wind expansion and the solar rotation, and exhibits spatial variation (e.g., sectors with the opposite directions of the radial component of the magnetic field, latitude dependence) and time variation (e.g., solar cycle dependence). Typical values of the IMF magnitude (in the sense of the mean field) $B_0$ turn out to be of the order of $3–4 \text{nT}$ at the Earth orbit (1 astronomical unit, hereafter au). Long-term measurements of the IMF by the Ulysses spacecraft show that the field magnitude of about $3–4 \text{nT}$ is typical not only in the solar ecliptic plane but also in the high-latitude regions (Forsyth et al., 1996). Of course, irregular or transient phenomena (such as coronal mass ejections or co-rotating interaction regions)

¹IMF is also referred to as the heliospheric magnetic field.
cause local, large-amplitude deviations from the mean field. Recent study by Henry et al. (2017) indicates that the IMF (at the Earth orbit) can be regarded as the Parker spiral type when the IMF is sufficiently inclined to the Earth orbital plane, either (1) \( B_x > 0.4B \) and \( B_y < -0.4B \) or (2) \( B_x < -0.4B \) and \( B_y > 0.4B \), where \( B_x \) is the sunward component of the magnetic field (GSE-X direction), \( B_y \) is the dawn-to-dusk component of the field (GSE-Y direction), and \( B \) is the magnetic field magnitude. The IMF can be more radial and of the Ortho-Parker spiral type (valid under \( |B_x| > 0.4B_t \)), where \( B_t \) denotes the transverse component of the magnetic field to the radial direction from the Sun, \( B_t = \sqrt{B_y^2 + B_z^2} \) or oriented more northward or southward \( |B_z| > 0.5B_t \).

Model construction of the IMF has immediate applications in the following plasma physical or astrophysical problems:

   Plasma and magnetic field in interplanetary space develop into turbulence. Early in situ measurements in 1960’s have already shown that the frequency spectrum of the fluctuation of the IMF is a power-law over a wide range of frequencies (typically in the mHz regime) (Coleman, 1968), and the spectral index is close to \(-5/3\) (Matthaeus et al., 1982; Tu and Marsch, 1995), known as the inertial-range spectrum of fluid turbulence. Properties of solar wind turbulence are extensively studied using in situ spacecraft such as Helios, Voyager, Ulysses, and the observational properties are documented in reviews by, e.g., Tu and Marsch (1995), Petrosyan et al. (2010), and Bruno and Carbone (2013). Solar wind is the only accessible natural laboratory of turbulence in collisionless plasmas, relevant to astrophysical applications to interstellar turbulence. Knowledge on the IMF structure is an important ingredient in turbulence modeling. In particular, the large-scale inhomogeneity or velocity shear are the driver of turbulence when the solar wind plasma evolves into turbulence. For example, the mean-field models of turbulence explicitly need the large-scale structure as an input (Yokoi and Hamba, 2007; Yokoi, 2011).

2. Charged dust motion.

   Dust grains in interplanetary space have typically a length scale of nanometers to micrometers, and are electrically charged by various processes, e.g., sticking of the ambient electrons onto the dust surface (which makes the dust charge state negative) or photo-electrons (which makes the charge state positive) (Shukla, 2001; Mann et al., 2014). Unlike the electrons or ions in the plasma, the charged dust grains undergo not only the gravitation attraction by the Sun and the planets and the Poynting-Robertson effect but also the electromagnetic interaction (Coulomb and Lorentz force). Combination of these forces results, e.g., in a long-time tilt of the orbital plane (on the time scale of 10 to 100 years), e.g., perihelion or apohelion shift from the solar ecliptic plane to the high-latitude region. Knowledge on the IMF structure is important because the orbital motion and the orbit drift can be tracked, either in a static IMF structure or in a time-evolving IMF structure (Grün et al., 1994; Mann et al., 2007, 2014; Czechowski and Mann, 2010; Lhotka et al., 2016).

3. Cosmic ray modulation.

   Cosmic ray consists mostly (more than 90\%) of protons. The spectrum of the cosmic ray is well characterized by a power-law as a function of the particle energy (kinetic energy, strictly speaking) with a peak at about 1 GeV and a
The number flux of the cosmic ray can be measured by the neutron monitors, and is known to be anti-correlated to the sunspot number variations with a period of about 22 years (cosmic ray modulation). The cosmic ray transport in the heliosphere is modeled by the convection-diffusion equation system, which can be treated both in a kinetic way based on the Boltzmann transport theory (Parker, 1965) and in a fluid-physical way using the continuity equation with the convection and diffusion terms (Duldig, 2001). See also the recent review by Potgieter (2013). The knowledge of IMF is important because the cosmic ray exhibits charged particles undergo drift motions in a curved, inhomogeneous magnetic field (i.e., curvature drift and grad-B drift), as pointed out by, e.g., Isenberg and Jokipii (1979). In fact, the 22-year variation of the cosmic ray modulation (as measured by the neutron monitors on the Earth ground) can be explained and theoretically reconstructed by including the IMF structure (Kóta and Jokipii, 2001a; Miyahara et al., 2010).

Here we review various models of the IMF with an emphasis on the hydrodynamic approach and the analytic expression. This review is intended to complement a more comprehensive review by Owens and Forsyth (2013). We limit our review to the kinematic approach in the sense that the magnetic fields behave passively and are frozen-in into the given plasma flow. The review is organized in a concise way by primarily taking the kinematic approach. There is an increasing amount of literatures and studies about the IMF and the modeling approach is becoming diverse, e.g., hydrodynamic, hydromagnetic, and kinetic.

We point out, however, that even in the simple kinematic approach, the IMF models are still illustrative and have various applications as introduced above.

We also limit our review to the analytic expression as much as possible. Analytic expression of the magnetic fields is a useful tool in space science, and has been constructed for various plasma domains or plasma phenomena in the solar system other than the solar wind: solar corona (Banaszkiewicz et al., 1998), coronal mass ejection (CME) (Isavnin, 2017), Earth’s magnetosphere (Katsiaria and Psillakis, 1987; Tsyganenko, 1990, 1995; Tsyganenko and Sitnov, 2007), and local interstellar medium surrounding the heliosphere (Röken, 2015). One can of course numerically solve the governing equations to reproduce the magnetic field and its dynamics more realistically, but the numerical treatment is not the scope of this review.

The advantage of the analytic or semi-analytic expression is that one can implement the magnetic field models by themselves for the theoretical studies of the solar system plasma phenomena. Verification of the magnetic field models is possible using the existing in situ spacecraft data from, e.g., the Helios, Voyager, and Ulysses missions as well as the upcoming measurements in interplanetary space by Parker Solar Probe (Fox et al., 2016), BepiColombo’s cruise in interplanetary space (Benkhoff et al., 2010), and Solar Orbiter (Müller et al., 2013).

2 Kinematic approach

We focus on the kinematic approach such that the flow pattern is given as an external field of a model field. The magnetic field is passive in the sense of the frozen-in field into the plasma. The reaction of the magnetic field onto the plasma motion (such as the Lorentz force acting on the plasma bulk flow) is not considered here.
2.1 Parker model

In this section we review the formulation of the original Parker spiral model of the interplanetary magnetic field.

2.1.1 Thermally-driven wind

As suggested by Biermann (1951, 1957) the solar gas outflows into interplanetary space. The existence of the radial outflow of the solar gaseous material, nowadays known as the solar wind, and the spiral structure of the IMF associated with the solar rotation were predicted by Parker (1958) before the confirmation by in situ spacecraft measurements. It is worth while to note that the spiral structure in interplanetary space was also indicated in the comet tail study by Alfvén (1957) as a beam extending away from the Sun. The solar wind is mainly composed of protons, electrons, and helium alpha particles (there are, in addition, heavier ions from the Sun and pickup ions from the local interstellar medium), and streams radially away from the Sun far beyond the orbits of the planets over distances of about 100 au. The solar wind first encounters the termination shock located before the heliopause, a boundary layer between the solar plasma and the local interstellar medium at a distance of about 110–160 au. At the Earth orbit distance (1 au), the solar wind velocity typically ranges between 300 km s\(^{-1}\) (referred to as the slow solar wind) to 700 km s\(^{-1}\) (the fast solar wind). During the coronal mass ejection events, the solar wind speed can reach about 1400 km s\(^{-1}\).

The Parker model treats the solar wind as a one-dimensional (in the radial direction), steady-state, iso-thermal thermally-driven stream. Basic equations are the continuity equation,

\[
\frac{d}{dr}(\rho U_r r^2) = 0,
\]

the momentum balance,

\[
U_r \frac{dU_r}{dr} + \frac{1}{\rho} \frac{dp}{dr} + \frac{G M_{\odot}}{r^2} = 0,
\]

and the adiabatic law or the equation of state,

\[
p = \rho c_s^2.
\]

Here \(\rho\) denotes the mass density, \(U_r\) the radial component of the flow velocity, \(r\) the distance from the Sun, \(p\) the gas pressure, \(G\) the gravitational constant, \(M_{\odot}\) the solar mass, and \(c_s\) the sound speed. Note that the sound speed is considered constant due to the assumption of the iso-thermal medium. Equations (1)–(3) can be reduced into the following form,

\[
U_r \frac{dU_r}{dr} \left( \frac{2c_s^2}{r} - \frac{GM_{\odot}}{r^2} \right) \left( 1 - \frac{c_s^2}{U_r^2} \right)^{-1} = 0.
\]

One sees immediately that Eq. (4) has a singularity at which \(U_r = c_s\) is satisfied. The flow speed reaches the sound speed (called the critical point or the sonic point) at

\[
r_c = \frac{GM_{\odot}}{2c_s^2}.
\]
The critical point is located about 6 solar radii for a (coronal) temperature of $1\text{ MK}$. Equation (4) exhibits difference types or classes of the flow velocity profile as a function of the distance from the Sun. Above all, a continuous flow acceleration over the sonic point meets the condition for the solar wind, i.e., acceleration in the subsonic domain ($r < r_c$) and further acceleration in the supersonic domain ($r > r_c$). See, e.g., Tajima and Shibata (2002) for a more detailed description about the Parker model.

At a larger distance than the critical radius $r_c$, the flow velocity has an asymptotic form,

$$U_r \simeq 2c_s \left( \ln \frac{r}{r_c} \right)^{1/2}.$$  

A comparison between the approximation of $U_r$ using (6) and a numerical solution of (4) is shown in Fig. 1. The solution shown in red and obtained for $T = 1\text{ MK}$, perfectly agrees with the analytical solution shown in dashed black. The Parker model thus predicts that the solar corona expands radially outward at subsonic velocities close to the Sun (within the critical radius), and the coronal gas is gradually accelerated to supersonic velocities further out. Hereafter we also use an expression of $U_{sw}$ for the magnitude of the solar wind velocity.
2.1.2 Spiral magnetic field

Using the angular velocity of the Sun, $\Omega_\odot$, the radial, polar, and azimuthal components of the solar wind velocity is given in the HG (heliographic) frame of reference as follows,

$$U_r = U_{sw}, \quad U_\theta = 0, \quad U_\phi = -\Omega_\odot r \sin \theta.$$  

A magnetic stream line satisfies the differential equation at a given polar angle $\theta$,

$$\frac{1}{r \sin \theta} \frac{dr}{d\phi} \sim \frac{U_r}{U_\phi} = -\frac{U}{\Omega_\odot r \sin \theta}. \quad (7)$$

We make use of a rough assumption that the flow speed is nearly constant over the critical radius beyond some distance $r > r_c$.

The field-line equation (Eq. 7) has then the solution as

$$r - r_0 = -\frac{U_{sw}}{\Omega_\odot} (\phi - \phi_0). \quad (8)$$

Here, the magnetic field line passes through the coordinate at $(r_0, \theta, \phi_0)$. The IMF is obtained from the divergence-free condition of the Maxwell equations,

$$\nabla \cdot B = 0.$$ 

That is, using the assumption of spherically symmetry, the IMF is

$$B_r (r, \theta, \phi) = B(r_0, \theta, \phi_0) \left( \frac{r_0}{r} \right)^2,$$

$$B_\theta (r, \theta, \phi) = 0,$$

$$B_\phi (r, \theta, \phi) = -B(r_0, \theta, \phi_0) \frac{\Omega_\odot r_0}{U_{sw}} \frac{r_0}{r} \sin \theta. \quad (9)$$

The transformation into the stationary frame (HGI, heliographic inertial) yields the same expression of the magnetic field as Eq. (9). Note that due to a Galilean transformation, the electric field has a convective contribution in the polar direction $\hat{\theta}$,

$$E = -U \times B = -U_{sw} B_\phi \hat{\theta}. \quad (10)$$

Realizations of the magnetic field lines in the Parker spiral model are shown for different (constant) solar wind speeds in Fig. 2. The angle between the the magnetic field line and Earth’s orbit is about $45^\circ$ for a typical solar wind speed of 400 km s$^{-1}$, and increases (becomes more radial) at a higher flow speed. Note that when considering the magnetohydrodynamic (MHD) effect, the above discussion is valid outside the Alfvén radius at which the flow speed reaches the Alfvén speed, $r_A \simeq 50 R_\odot = 0.25$ au, where $R_\odot$ is the solar radius.

We rewrite (9) into a simpler form as

$$B_r = B_0 \left( \frac{r_0}{r} \right)^2,$$

$$B_\phi = -r_0 B_0 \left( \frac{r_0}{r} \right) \frac{\Omega_\odot \cos \theta}{U_{sw}}, \quad (11)$$
where $B_0 = B(r_0, \theta, \phi_0)$ (Meyer-Vernet, 2012).

We note that in (11) the latitude $\vartheta$ (measured from the equator) is related to the polar angle $\theta$ (measured from the rotation axis) by $\theta = \pi - \vartheta$. By identifying or defining the radial and tangential components as $B_R = B_r$ and $B_T = B_\phi$, respectively, it is straightforward to transform the Parker spiral field into the RTN system as

$$\begin{align*}
B_R &= B_0 \left(\frac{r_0}{r}\right)^2, \\
B_T &= -r_0 B_0 \left(\frac{r_0}{r}\right) \frac{\Omega_\odot \sin \theta}{U_{sw}}.
\end{align*}$$

(12)

Note that the normal component vanishes, $B_N = 0$, because the Parker model does not include the polar component like the dipolar field of the Sun.
2.1.3 Spiral angle

The distance to the surface on which an azimuthal angle of 45° is realized (or $B_{\theta} \simeq B_{r}$) is approximately located

$$r \simeq \frac{U_{sw}}{\Omega_{\odot}} \sin \theta.$$  

Using the rotation period of the Sun 25.38 days (equivalent to an angular velocity of $\omega = 2.865 \times 10^{-6} \text{rad s}^{-1}$) and the flow speed $U_{sw} \simeq 430 \text{km/s}$, the transition from the radially-dominant to the azimuthally-dominant magnetic field indeed happens around $r = 1 \text{ au}$. The transition distance is displayed as a function of the flow speed in Fig. 3 for three different solar rotation periods, 24.47 days, 25.38 days, and 26.24 days.

Alternatively, the Parker spiral model can be formulated in terms of the spiral angle $\psi$:

$$\tan \psi = \frac{\Omega_{\odot}(r - R_{\odot}) \sin \theta}{U_{sw}},$$  \hspace{1cm} (13)
In this setting, the magnetic field $B$ is, by using the unit vectors in the radial direction $e_r$ and in the azimuthal direction $e_\phi$, given as

$$B = B_0 \left( \frac{r_0}{r} \right)^2 (e_r - \tan \psi e_\phi).$$  \hspace{1cm} (14)

In this formulation the magnitude of the magnetic field is estimated as

$$B = B_0 \left( \frac{r_0}{r} \right)^2 \sqrt{1 + \tan^2 \psi}$$ \hspace{1cm} (15)

### 2.1.4 Vector potential

The magnetic vector potential $A$ for the Parker spiral magnetic field under the Coloumb gauge $\nabla \cdot A = 0$ can analytically be evaluated (Bieber et al., 1987). The vector potential in the following form,

$$A_r = \frac{2a \Omega_{\odot}}{3U_{sw}} \left( 1 - \frac{3x}{2} - x \ln(1 + x) \right)$$  \hspace{1cm} (16)

$$A_\theta = \frac{2a \Omega_{\odot}}{3U_{sw}} \sin \theta \left( \frac{x}{1 + x} + \ln(1 + x) \right),$$  \hspace{1cm} (17)

$$A_\phi = \frac{a}{r \sin \theta} (1 - x),$$ \hspace{1cm} (18)

corresponds to the IMF as

$$B_r = \frac{a}{r^2} \frac{\cos \theta}{|\cos \theta|}$$  \hspace{1cm} (19)

$$B_\theta = 0$$  \hspace{1cm} (20)

$$B_\phi = -\frac{a \Omega_{\odot}}{U_{sw}} \frac{\sin \theta \cos \theta}{|\cos \theta|}$$ \hspace{1cm} (21)

Here $a$ is a free parameter proportional to the magnitude of the magnetic field in units of nT au$^2$ (for example, $a = 3.54$ nT au$^2$ produces a magnetic field of 5 nT at 1 au) and $x = |\cos \theta|$. The polar component of the vector potential can be multiplied by a scalar function $f(\theta)$ to improve the accuracy of the model as $A_\theta \rightarrow f(\theta)A_\theta$.

Another formulation of the vector potential (again, under the Coulomb gauge) is to introduce a scalar potential as

$$\Phi_C = -\frac{2a \Omega_{\odot}r}{3u} \left( 1 - \frac{3x}{2} - x \ln(1 + x) \right),$$  \hspace{1cm} (22)

which yields the following vector potential (Webb et al., 2010),

$$A = a \left( \frac{1 - |\cos \theta|}{r \sin \theta} e_\phi - \frac{f(\theta) \Omega_{\odot} \sin \theta}{U_{sw}} e_\theta \right).$$ \hspace{1cm} (23)

Of course, in the both cases, Eqs. (16)–(18) and (23), the magnetic field is obtained by the definition of the vector potential $B = \nabla \times A$. The electrostatic potential for the convective electric field $E = -U \times B = -\nabla \Phi$ is

$$\Phi = -a \Omega_{\odot} \cos \theta.$$  \hspace{1cm} (24)
The magnetic field lines for the Parker spiral model are shown in Fig. 4. Black lines have been calculated by the intersection of the surfaces $\alpha = \text{const}$ and $\beta = \text{const}$, where $\alpha$, $\beta$ define the Euler potentials of the vector field. See text.

$$\alpha = -a|\cos \theta|, \quad \beta = \phi + \frac{\Omega \odot r}{U_{sw}} - \Omega_\odot t.$$  

(25)

for the sake of convenience the choice $a = 1$, $t = 0$, and $\Omega_\odot = U_{sw} = 1$ is made to provide the topology of the problem: $\alpha$ defines a cone (in green) that intersects a shell (in red) defined by $\beta$. Intersection lines define the magnetic field lines of the Parker model.

Figure 4. Magnetic field lines (black curves) in the Parker spiral model for different latitude angles $\theta$. Curves are defined as the intersection of the surfaces $\alpha = \text{const}$ and $\beta = \text{const}$, where $\alpha$, $\beta$ define the Euler potentials of the vector field. See text.
2.2 Generalization of the Parker model

The Parker spiral model well approximates the mean, and large scale structure of the interplanetary magnetic field of our solar system. However, it fails to describe the three-dimensional geometry and evolution in time on various scales.

2.2.1 Latitudinal dependence

The Parker model does not recognize the sign reversal of the dipolar magnetic field over the north and the south hemispheres, the divergence-free nature of the magnetic field is not well represented. The hemispheric sign reversal can be incorporated into the Parker model as follows (Webb et al., 2010):

\[ B = \frac{af(\theta)}{r^2} \left(e_r - \frac{\Omega r \sin \theta}{u} e_\phi \right). \]  

(26)

Here, the constant \( a \) and function \( f(\theta) \) are given by:

\[ a = \sigma B_0 r_0^2, \quad f(\theta) = 1 - 2H(\theta - \pi/2) = \cos \theta \left| \cos \theta \right|, \]

where \( \sigma = \pm 1 \) defines the polarity of the magnetic field in the northern hemisphere of the sun, and \( f(\theta) \) is the Heaviside step function with the property \( f(\theta) = +1 \) for \( 0 < \theta < \pi/2 \) and \( f(\theta) = -1 \) for \( \theta > \pi/2 \).

A more elaborated analytic model is proposed along with the Ulysses measurements over the solar polar regions (Zurbuchen et al., 1997; Forsyth et al., 2002). The three-dimensional model allows non-zero field in the polar component, and is expressed as \(^2\)

\[ B_r = B_0 \left( \frac{r_0}{r} \right)^2, \]

(27)

\[ B_\theta = \frac{B_0 r_0^2}{u_{sw} r} \omega \sin \beta \sin \left( \phi + \frac{r \Omega_\odot}{U_{sw}} - \phi_0 \right), \]

(28)

\[ B_\phi = -\frac{B_0 r_0^2}{u_{sw} r} \left[ \Omega_\odot \sin \theta - \omega \left( \cos \beta \sin \theta + \sin \beta \cos \theta \cos \left( \phi + \frac{r \Omega_\odot}{U_{sw}} - \phi_0 \right) \right) \right]. \]  

(29)

where \( B_0 \) is the magnetic field magnitude at the source surface located at heliospheric distance \( r = r_0 \), \( \omega \) the differential rotation rate of the magnetic field line foot points, \( \beta \) the polar angle at which a field line originating in the rotational pole crosses the source surface and is related to the angle between the solar magnetic dipole axis and the rotation axis, \( \phi_0 \) the heliographic longitude of the plane defined by the rotation and magnetic axes. The source magnetic field is defined at \( r = r_0 \).

The angle \( \phi = \phi_0 \) occurs in the plane defined by the rotation axis and the magnetic axis of the Sun. Angle \( \beta \) is the polar angle where the field line \( p \) crosses the source surface (from the heliographic pole). The angle \( \beta \) can be calculated in the model by Fisk (1996) for a given orientation \( \alpha \) of the magnetic axis \( M \) and a given non-radial expansion. For the configuration discussed by Fisk (1996), the value of \( \beta \) is about 30°.

\(^2\)Here, \( \alpha, \beta \) are constants different from the constants used in the definition of Euler potentials in previous sections.
2.2.2 Northward component

The IMF can have a non-zero polar (or latitudinal) component, e.g., from the solar dipolar field. Generalization of the Parker model to the non-zero polar component case ($B_\theta \neq 0$) is based on the analysis by Forsyth et al. (1996). Let $\phi_B$ be the azimuthal angle that the projection of the IMF vector onto the R–T plane makes with the R axis in the right-handed sense, and $\delta_B$ be the meridional angle of the IMF to the R–T plane. These angles are defined in terms of the magnetic field components (Forsyth et al., 1996):

$$\tan \phi_B = B_T / B_R$$
$$\sin \delta_B = B_N / B,$$  \hspace{1cm} (30)

where

$$B = \sqrt{B_R^2 + B_T^2 + B_N^2}.$$  \hspace{1cm} (31)

The azimuthal angle of the spiral field $\phi_P$ that the tangent to the ideal Parker spiral magnetic field makes with the radially outward direction at a position in interplanetary space specified by radial position $r$ and heliographic latitude $\delta$ is then given by:

$$\tan \phi_P = \frac{U_\phi - r\Omega \cos \delta}{U_r}. $$  \hspace{1cm} (31)

On the assumption that $U_\phi$ is small, $\phi_P$ turns out to be negative. A magnetic field with a direction in agreement with the Parker spiral model will have either $\phi_B = \phi_P$ in a region of outward polarity or $\phi_B = 180^\circ + \phi_P$ in a region of inward polarity field. In both regions the Parker model predicts that an ideal magnetic field has a meridional angle $\delta_B = 0^\circ$ with respect to the R–T plane. Therefore, up to the second order in $B_N$ the sine of the meridional angle $\delta_B$ according to the second equation in (30) is given by

$$\sin \delta_B \approx \frac{B_N}{\sqrt{B_R^2 + B_T^2}}.$$  \hspace{1cm} (32)

If we combine the first of (30) together with (32) and solve for $B_T$ and $B_N$ we find up to $O(B_N^2)$:

$$B_T = -B_0 \left( \frac{r_0}{r} \right)^2 \frac{(U_\phi - r\Omega \cos \delta)}{U_r},$$

$$B_N = B_0 \left( \frac{r_0}{r} \right)^2 \sqrt{1 + \frac{(U_\phi - r\Omega \cos \delta)^2}{U_r^2}} \sin \delta_B,$$  \hspace{1cm} (33)

where we substituted $B_R$ by $B_0$ in Eq. (11),

$$B_R = \left( \frac{r_0}{r} \right)^2.$$  \hspace{1cm} (34)

Equations (33)–(34) provide a type of the Parker spiral magnetic field with the generalization to a non-zero normal component $B_N \neq 0$ parameterized by $\delta$ and $\delta_B$. For $\delta_B = 0^\circ$ and ignoring the azimuthal component of the solar wind $U_\phi$, the model
reproduces the Parker model, i.e., Eq. (11) :
\[
B_R = B_0 \left( \frac{r_0}{r} \right)^2 ,
B_T = - \left( \frac{r_0}{r} \right) r_0 B_0 \Omega_\odot \cos \delta ,
B_N = 0 .
\] (35)

5 Another way of generalization is to use the power-law dependence using the power-law index \( \kappa \) as a free parameter (Lhotka et al., 2016),
\[
B_R = B_{R0} \left( \frac{r_0}{r} \right)^2 b_R(t) ,
B_T = B_{T0} \left( \frac{r_0}{r} \right) b_T(t) ,
B_N = B_{N0} \left( \frac{r_0}{r} \right)^\kappa b_R(t) .
\] (36)

Here, \( B_{R0} \), \( B_{T0} \), and \( B_{N0} \) are the mean magnetic field. \( b_R \), \( b_T \), and \( b_N \) can be time-dependent such as the solar cycle (see section 2.2.3). The power-law index \( \kappa \) is a free parameter and determines the dependence of \( B_N \) on the inverse distance from the Sun \( 1/r \).

2.2.3 Solar cycle dependence

The solar cycle is a periodic change in the sunspot number over 11 years. Plasma physically, the solar cycle is more associated with the magnetic activity of the Sun with a period of 22 years (the magnetic polarity is reversed after one sunspot cycle). During solar maximum the entire magnetic field of the Sun flips, thus alternating the polarity of the field every solar cycle. The solar (magnetic) activity is diverse such as solar radiation, ejections of solar material, and the number and the size of sunspots and the occurrence rate of solar eruptions. As a consequence, the periodic change in the solar magnetic field (or dipolar axis) affects the polarity of the IMF as well. To include the time dependent effect Kocifaj et al. (2006) suggests the following magnetic field model,
\[
B_R = B_0 \left( \frac{r_0}{r} \right)^2 \cos \left( \frac{\pi t}{11[yr]} + \phi_0 \right) ,
B_T = -B_0 \left( \frac{r_0}{r} \right) \cos \vartheta \cos \left( \frac{\pi t}{11[yr]} + \phi_0 \right) .
\] (37)

Here, \( \vartheta \) is again latitude with \( \theta = \pi - \vartheta \). The authors define the magnetic field in the RTN coordinate system with
\[
B = B_R e_R + B_T e_T ,
\]
and \( e_T = \omega_{\text{mag}} \times e_R \), where \( \omega_{\text{mag}} \) defines the magnetic axis of the Sun. If we assume that \( \omega \) coincides with the rotation axis of the Sun then \( B_T = -B_\phi \) with \( B_\phi \) given in Eq. (11). However, in comparison with the second equation in Eq. (11), the second equation in Eq. (26) differs by a factor \( r_0 \Omega_\odot/U_r \) in addition to the inclusion of the time dependent terms. However, assuming solar wind speed \( U_{sw} \approx 450 \text{ km s}^{-1} \), and solar rotation rate \( \Omega_\odot \approx 2\pi/24.47 \text{ day}^{-1} \) this factor becomes close to unity at \( r_0 = 1 \) au.
Two additional effects can further be incorporated into the IMF model, the polarity $A_{\text{mag}}$ and the tilt angle $\theta_{\text{tlt}}$. The polarity $A_{\text{mag}}$ is defined such that a case of $A_{\text{mag}} > 0$ corresponds to the magnetic fields pointing outward from the Sun in the northern hemisphere (the angle between the magnetic axis and the solar rotation axis is below 90°), and a case of $A_{\text{mag}} < 0$ is in the opposite sense to $A_{\text{mag}} > 0$. Using the polarity $A_{\text{mag}}$, the Parker spiral magnetic field is given by the following equation (Jokipii and Thomas, 1981):

$$B = \frac{A_{\text{mag}}}{r^2} (e_r - \Gamma e_\phi) \times 
\left\{ 1 - 2H \left[ \theta - \left( \frac{\pi}{2} + \theta_{\text{tlt}} \sin \left( \phi - \frac{r \Omega_\odot}{U_{sw}} \right) \right) \right] \right\}$$

(38)

where $H$ is the Heaviside step function. $\Gamma$ is defined as

$$\Gamma = \frac{r \Omega_\odot \sin \theta}{U_{sw}}.$$

(39)

The polarity $A_{\text{mag}}$ is expressed in units of magnetic flux (cf. Eq. 14). An equivalent formulation of Eq. (38) is as follows (Kota and Jokipii, 1983):

$$B = \frac{A_{\text{mag}}}{r^2} \left( e_r - \frac{r \Omega_\odot \sin \theta}{U_{sw}} e_\phi \right) [1 - 2H(\theta - \theta^*)]$$

(40)

$$\cot \theta^* = -\tan \theta_{\text{tlt}} \sin \phi^*$$

(41)

where $\phi^*$ is the azimuthal angle in the co-rotating frame at an angular speed of the solar rotation,

$$\phi^* = \phi + \frac{r \Omega_\odot}{U_{sw}}.$$

(42)

The tilt angle $\theta_{\text{tlt}}$ is larger at near solar maximum and smaller at near solar minimum (Thomas and Smith, 1981), and typically varies from 75 degrees at high level of solar activity to 10 down to 3 degrees during solar minimum activity. A model of tilt angle variation over a 22-year solar cycle was constructed by Jokipii and Thomas (1981), Kota and Jokippi (1983) as follows:

$$\theta_{\text{tlt}} = \theta_{t0} + \theta_{t1} \cos \left( \frac{2\pi t}{T} \right)$$

(43)

where $\theta_{t0} = 20^\circ$, $\theta_{t1} = 10^\circ$, and $T = 11$ yr. The tilt angle $\theta_{\text{tlt}}$ is set to be at sunspot maximum at $t = 0$.

The wavy, flapping shape of the heliospheric current sheet is expressed by the equation for the polar angle as follows (Jokipii and Thomas, 1981):

$$\theta_{\text{cs}} = \frac{\pi}{2} + \sin^{-1} \left[ \sin \theta_{\text{tlt}} \sin \left( \phi - \phi_0 + \frac{r \Omega_\odot}{U_{sw}} \right) \right]$$

(44)

$$\approx \frac{\pi}{2} + \theta_{\text{tlt}} \sin \left( \phi - \phi_0 + \frac{r \Omega_\odot}{U_{sw}} \right)$$

(45)

The approximation in Eq. (45) is valid for $\theta_{\text{tlt}} \ll 1$ rad (up to about 30°).
A sketch of the topology of the heliospheric current sheet is shown in Fig. 5, where the magnetic field is discontinuous, i.e. for vanishing $\theta - \theta^* = 0$ in $H(\theta - \theta^*)$. For small values of $\theta_{\text{clt}}$ the sheet is close to the plane defined in terms of the solar equator (left) while for larger values ($\theta_{\text{clt}} = 20^\circ$) the wavy structure of the 'ballerina skirt' is found to be much more pronounced.

The drift motion depends on the sign of $q A_{\text{mag}}$, a combination of the electric charge of the particle and the polarity of the solar magnetic field. During the period of $q A_{\text{mag}} > 0$, the time variation of the cosmic ray flux shows a flatter maximum, while during $q A_{\text{mag}} < 0$ the time variation of the cosmic ray flux shows a shape maximum, see, e.g. Jokipii and Thomas (1981) or Kota and Jokipii (1983).

3 Further models and effects

3.1 Magnetohydrodynamic models

The models of the solar wind and the interplanetary magnetic field can be extended from kinematic or hydrodynamic treatments to magnetohydrodynamic (MHD) treatments. An overview of the MHD wind models is given by Tajima and Shibata (2002). Various magnetic effects are introduced in the MHD picture, e.g., the Alfvén velocity as a characteristic propagation speed (the Parker model, in contrast, recognizes the sound speed as a characteristic propagation speed) and the associated critical radius, collimation of the flow toward the rotation axis by magnetic pinching in the twisted field geometry.
One-dimensional treatment

An MHD model is proposed for an axi-symmetric, one-dimensional, centrifugal force driven wind on the solar equatorial plane (Weber and Davis, 1967). Six variables are determined as a function of the radial distance (mass density $\rho$, radial and azimuthal components of flow speed, $U_r$ and $U_\phi$, and that of the magnetic field, $B_r$ and $B_\phi$, and pressure $p$) using six equations (continuity equation, magnetic flux conservation, force balance, induction equation, adiabatic pressure, and energy conservation) and six integral constants (mass flux, magnetic flux, angular velocity of the Sun, Alfvén radius, entropy, and total energy). The Alfvén radius is defined as the radius at which the flow velocity reaches the Alfvén velocity in the radial component, $U_r = V_A r$. At larger distances from the Sun, the solution is given asymptotically as

$$\rho \propto r^{-2}$$

$$U_r \rightarrow U_\infty$$

$$B_r \propto r^{-2}$$

$$B_\phi \propto r$$

The magnetic field becomes more azimuthal and thus twisted with increasing distance, $B_\phi/B_r \propto r$.

The momentum balance equation by Parker (1958) is extended to including the effect of magnetic field and Alfvén wave heating rate (Woolsey and Cramer, 2014; Comišel et al., 2015):

$$\frac{1}{U} \frac{dU}{dr} \left( U^2 - U_c^2 \right) = -U_c^2 \frac{d}{dr} \ln B - \frac{c_s^2}{2} \frac{d}{dr} \ln T + \frac{Q_A}{2\rho(U + V_A)} \frac{GM_\odot}{r^2}. \tag{50}$$

Here $Q_A$ denotes the Alfvén wave heating rate. $U_c$ is the critical speed

$$U_c^2 = c_s^2 + \frac{W_A}{4\rho} \frac{3U + V_A}{U + V_A},$$

where $W_A$ is the energy density of the Alfvén waves including the perpendicular fluctuation components of the flow velocity $\delta U_\perp$ and that of the magnetic field $\delta B_\perp$,

$$W_A = \frac{1}{2} \rho \delta U_\perp^2 + \frac{\delta B_\perp^2}{2\mu_0}. \tag{52}$$

Two-dimensional treatment

In the two-dimensional picture, the energy conservation (the generalized Bernoulli equation) and the conservation law perpendicular to the magnetic field (the generalized Grad-Shafranov equation) are derived using the force balance equation among the advection of the flow itself (flow nonlinearity such as steepening and eddies), the pressure gradient, the Lorentz force, and the gravitational attraction by the Sun, the mass flux conservation, the induction equation, and the adiabatic condition along the flow (Heinemann and Olbert, 1978; Sakurai, 1985; Lovelace et al., 1986). The generalized Grad-Shafranov equation cannot be solved analytically but needs to be solved numerically. It is found that the wind becomes collimated toward the rotation axis of
the Sun (or the star) by the magnetic pinching of the spiral or twisted field. In fact, any stationary, axi-symmetric magnetized wind collimates toward the rotation axis at large distances (Heyvaerts and Norman, 1989).

3.2 More ingredients

Solar wind models can further be improved by considering turbulent diffusion and pickup ions.

5 Turbulent diffusion

Turbulence on smaller scales serves as an energy sink to large-scale mean fields. A convenient way to incorporate the turbulence effect into the solar wind model is to introduce an effective viscosity (called the turbulent viscosity) in the following form (Yokoi, 2006; Yokoi and Hamba, 2007; Yokoi et al., 2008):

\[ \nu_{\text{turb}} = C \frac{K^2}{\epsilon}, \] (53)

where \( K \) denotes the total fluctuation energy (a sum of the kinetic fluctuation energy and the magnetic fluctuation energy) and \( \epsilon \) is the dissipation rate of turbulence energy. MHD flow models can be extended to incorporate the electromotive force into the MHD equations with the magnetic growth term (or referred to as the alpha effect), the turbulent diffusion term, and the cross helicity term (Yokoi, 2006).

A more rigorous treatment is to solve two sets of equations, one for the large-scale mean fields and the other for the small-scale turbulent fields. This task can be achieved either analytically using the two-scale direct interaction approximation (Yokoi et al., 2008) or numerically (Usmanov et al., 2012, 2014, 2016).

Pickup ions

Pickup ions from interstellar neutral hydrogen atoms are one of the ingredients to the solar wind, and contribute to additional mass of the plasma, which results in deceleration of the solar wind expansion and in increase in the plasma temperature. Pickup process originate in charge exchange with the solar wind protons and photoionization by the solar radiation. Steady-state MHD equations for the wind including pickup ions are introduced by Whang (1998), and are numerically implemented to simulation studies for a three-component fluid (thermal protons, electrons, pickup protons) by Usmanov and Goldstein (2006); Usmanov et al. (2014) and for a four-component fluid by adding interstellar hydrogen (Usmanov et al., 2016).

3.3 Stellar wind and interstellar space

For stellar winds, various outflow models have been proposed. They are spherically symmetric and in a steady state. Stellar winds can be detected by the spectroscopic investigation. A line spectrum becomes distorted to blueshifted absorption and redshifted emission by the retarding stellar wind (away from the observer), known as the P Cygni profile. One type of the stellar wind models is the Lucy model (Lucy, 1971):

\[ U = U_t \left[ 1 - \frac{(1-a)r^*}{r} - \frac{a^2 r^*}{r^2} \right]^{1/2}, \] (54)
where \( a \) is a free parameter with \(-1 < a < 1\). Equation (54) satisfies the conditions of zero speed at the stellar surface, \((U = 0\) at \(r = r_\ast\)) and asymptotic behavior at very large distances from the star (\(u \frac{dU}{dr} \propto r^{-2}\) as \(r \to \infty\)). \(U_t\) is the terminal flow velocity. The flow speed increases monotonously as a function of the radius, \(U > 0\) and \(\frac{dU}{dr} > 0\). The other type is a variant of the Lucy model (Kudritzki and Puls, 2000):

\[
\frac{u}{u_\infty} = \left(1 - \frac{r_\ast}{r}\right)^\beta
\]

(55)

where the constant \(b\) is the flow velocity at the inner boundary of the stellar wind. An even more simplified expression is (Lamers, 1998)

\[
\frac{u}{u_\infty} = \left(1 - \frac{r_\ast}{r}\right)^\beta
\]

(56)

where \(u_\infty\) is the asymptotic, termination flow speed and \(r_\ast\) the stellar radius. \(\beta\) is a free parameter, and is empirically chosen as \(0.5 \leq \beta \leq 4\) (Sapar et al., 2003).

### 4 Summary and conclusions

There is an increasing amount of models for the interplanetary magnetic field. Starting with the Parker model, the magnetic field model can be extended to include the latitudinal dependence, the northward component, the time-dependence, and the polarity and tilt effect even in the analytic treatment. Which model to choose would depend on the application, e.g., if the solar cycle is to be included or not, or if the latitudinal dependence is to be or not. In the temporal sense, cosmic ray diffusion has the shortest time scale, about 13 hours for relativistic particles nearly at the speed of light to travel over 100-au distance in the heliosphere. In contrast, plasma turbulence evolves together with the solar wind, and the time scale is intermediate, being of the order or days (cf. the solar wind travel time from the Sun to the Earth orbit, 1 au, is about 100 hours or roughly 4 days. Charged dust motions and modulation of the cosmic ray flux in the heliosphere evolve on the longest time scale among the three applications, of the order of of years (secular variation of the orbital parameters).

The accuracy or the uncertainty of the reviewed models need to be verified using in situ magnetic field measurements from the previous, current, and upcoming spacecraft missions. Above all, the magnetic field in the inner heliosphere will be extensively studied with Parker Solar Probe, BepiColombo (in particular, the cruise-phase measurements), and Solar Orbiter.

It is interesting to note that the analytic expression is also available for the coronal magnetic field (during the solar minimum) and the local interstellar magnetic field surrounding the heliosphere. Hence, naively speaking, one may expect to construct a more complete model of the magnetic field from the Sun to the local interstellar medium. Such a model, once smoothly and rationally connected from one region to another, enables one to improve the accuracy of theoretical studies on plasma turbulence evolution, charged dust motions, and diffusion of cosmic ray and energetic particles.
