Abstract. Jets in the subsolar magnetosheath are localized enhancements in dynamic pressure that are able to propagate all the way from the bow shock to the magnetopause. Due to their excess velocity with respect to their environment, they push slower ambient plasma out of their way, creating a vortical plasma motion in and around them. Simulations and case study results suggest that jets also modify the magnetic field in the magnetosheath on their passage, aligning it more with their velocity. Based on MMS jet observations and corresponding superposed epoch analyses of the angles ϕ between the velocity and magnetic fields, we can confirm that this suggestion is correct. However, the effect is small: Typically, reductions in ϕ of only 10° are observed at jet core regions, where the jets' velocities are largest. Furthermore, time series of angles ϕ pertaining to individual jets significantly deviate from the superposed epoch analysis results. They usually exhibit large variations over the entire range of ϕ : 0° to 90° . This variability is commonly somewhat larger within jets than outside, masking the systematic decrease in ϕ at core regions of individual jets.

1 Introduction

The region downstream of the Earth's bow shock, the magnetosheath, is oftentimes permeated by localized plasma entities of significantly enhanced dynamic pressure, so-called magnetosheath jets (for a recent review, see Plaschke et al., 2018). Within those jets, the dynamic pressure can easily exceed values measured in the pristine solar wind, and a significant fraction of jets even feature super-magnetosonic plasma velocities (Savin et al., 2008; Hietala et al., 2009; Plaschke et al., 2013; Savin et al., 2014). Thus, jets are highly distinctive phenomena in the subsolar magnetosheath.

Jets are known to occur more often downstream of the quasi-parallel shock (Archer and Horbury, 2013; Plaschke et al., 2013, 2016). In the subsolar magnetosheath, their occurrence is, hence, enhanced when the interplanetary magnetic field (IMF) points in a quasi-radial direction, i.e., when the angle between the IMF and the Earth-Sun-line – the IMF cone angle – is low. Under these conditions, shock-reflected particles are able to propagate along the IMF into the region upstream of the shock, where the particles then interact with the solar wind. The interaction region, called foreshock, exhibits localized magnetic field and plasma structures and waves that are convected back to the shock, merge into it and, thus, continuously form and reform it (e.g., Schwartz and Burgess, 1991; Omidi et al., 2005; Blanco-Cano et al., 2006a, b). As a result, the quasi-parallel shock may be regarded as undulated or rippled. At the inclined surfaces of such ripples, solar wind plasma may be less decelerated and

heated, yet still compressed and focused, yielding coherent high-speed jets within slower ambient plasma in the downstream magnetosheath region (Hietala et al., 2009, 2012). A second, smaller group of jets appears to be associated to the passage of IMF discontinuities, in particular when the character of the shock changes from quasi-perpendicular to quasi-parallel (Dmitriev and Suvorova, 2012; Savin et al., 2012; Archer et al., 2012; Plaschke et al., 2017). In this context, jets have also been associated to hot flow anomalies (HFAs) that can occur when an IMF discontinuity interacts with the bow shock (Schwartz et al., 2000; Omidi and Sibeck, 2007).

Jets link the processes in the foreshock and at the bow shock with effects at the magnetopause, in the magnetosphere, and on ground. Upon impact on the magnetopause, jets are able to indent the boundary significantly (e.g., Shue et al., 2009; Amata et al., 2011), launching waves on the surface and in the magnetosphere (Plaschke and Glassmeier, 2011; Archer et al., 2013a, b; Archer et al., 2019), and/or triggering magnetic reconnection (Hietala et al., 2018). Effects of the interaction are also visible from the ground, as ionospheric flow enhancements, geomagnetic variations, or dayside auroral activity (Hietala et al., 2012; Dmitriev and Suvorova, 2012; Han et al., 2016, 2017; Wang et al., 2018). Jets are very common in the magnetosheath. In general, large scale jets - larger than 2 Earth radii (R_E) in diameter - hit the magnetopause approximately every 20 minutes. Under low IMF cone angle conditions, this rate increases to approximately one jet every 6 minutes (Plaschke et al., 2016). Note that typical jet scale sizes are on the order of $1 R_E$.

Recently, the inner structure of jets and their interaction with ambient magnetosheath plasma and fields have gotten more attention (Karimabadi et al., 2014; Plaschke et al., 2017; Plaschke and Hietala, 2018): When jets plough through slower ambient plasma, that latter plasma is pushed out of the way. Behind the jets, ambient plasma moves in to refill the wake. In addition, the fast motion of jets through slower ambient plasma may modify the magnetic field inside jets and in their vicinity, as seen in simulations by Karimabadi et al. (2014): The field may become more aligned with the plasma flow inside jets (see Figure 1a). This hypothesis is supported by Plaschke et al. (2017), who found magnetic field and velocity measurements to be correlated within 18 jets that occurred during an hour-long interval. However, their case study could not yield conclusive evidence on how the magnetic field changes, on average, on the passage of a jet. The purpose of this paper is to obtain and present this information.

2 Data and Methods

This study is based on jet observations by the four Magnetospheric Multiscale (MMS) spacecraft (Burch et al., 2016), made during the first and second dayside seasons of the mission (between 1 September 2015, the start of mission phase 1a, and 1 May 2017, the end of phase 2a). The MMS spacecraft were launched on 13 March 2015 into a highly elliptical, and nearly equatorial orbit. The initial apogee distance of the spacecraft from Earth was $12 R_E$. This distance stayed the same in 2015 and 2016, and was raised in the first few months of 2017 to follow the dawn magnetopause as the orbit swept westwards. Consequently, the spacecraft spent significant time in the vicinity of the subsolar magnetopause, flying in close tetrahedral configuration with spacecraft separations between 60 and less than 10 km, to achieve their primary goal: to investigate the small-scale physics of

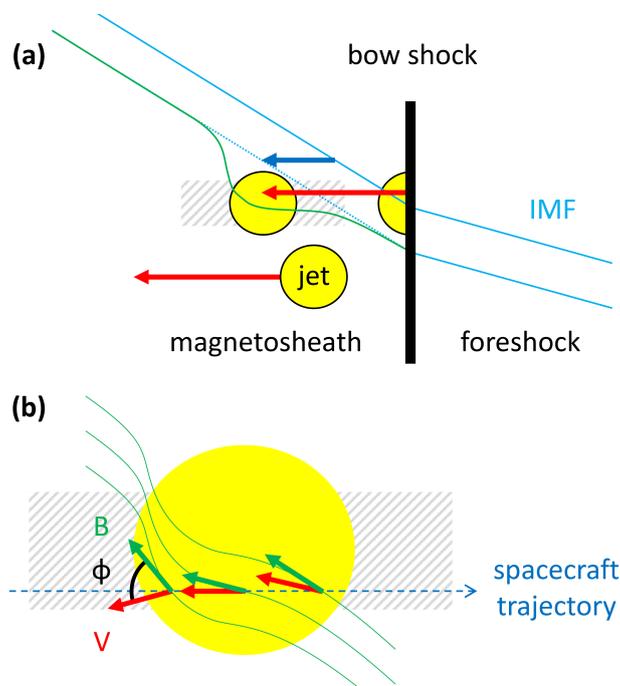

Figure 1. Top panel (a): Sketch of how magnetic fields in the magnetosheath may be modified by the motion of fast plasma jets. Velocities of jets and ambient plasmas are illustrated by red and blue arrows, respectively. In this paper, magnetic and velocity fields within the hatched area are evaluated. After Figure 12 in Plaschke et al. (2017). Bottom panel (b): Close-up on a jet. Green and red arrows show local directions of the magnetic field B and velocity V measured by a spacecraft on its trajectory through the jet. The angle between B and V is $\phi_{B,V}$.

magnetic reconnection. While in the magnetosheath, they observed numerous jets close to the magnetopause, where jets should be in an evolved state, making it more likely for jet-related magnetic field variation patterns to become apparent.

To obtain a data set of jet observations by the MMS spacecraft, we follow the steps described in detail in Plaschke et al. (2013). We preselect intervals where the MMS spacecraft were located within a 30° wide cone, centered at Earth and open to the Sun, at distances above $7 R_E$ and below $18 R_E$ from the Earth's center. Within those preselected intervals, magnetosheath intervals are identified by the ion density surpassing twice the density in the solar wind. Here, we use MMS ion density moments from the Fast Plasma Investigation (FPI, Pollock et al., 2016). These are compared to proton density measurements from NASA's OMNI high resolution data set (King and Papitashvili, 2005), averaged over 5 minutes preceding any time of interest. Note that OMNI measurements are based on solar wind monitor data from, e.g., the Advanced Composition Explorer (ACE) and Wind spacecraft, propagated to the bow shock nose. The 5 minute averaging accounts for further propagation to the positions of the MMS spacecraft, closer to the magnetopause. In addition, within magnetosheath intervals the ion omnidirectional energy flux density of 1 keV ions (measured also by FPI) shall be larger than that of 10 keV ions, to exclude magnetospheric observations. The magnetosheath intervals shall be at least 2 minutes long and all quantities of interest shall be available, i.e., magnetic field measurements by the MMS Fluxgate Magnetometers (FGM, Russell et al., 2016; Torbert et al.,

2016), ion moments and distribution functions by FPI, and OMNI solar wind magnetic field and ion moments. Therewith, MMS 1 to 4 yield a total of 4345.5 hours of magnetosheath data in 9375 intervals. Note that the intervals are almost equally distributed among the four MMS spacecraft, due to their close configuration: MMS 1, 2, 3, and 4, contribute 2376, 2370, 2279, and 2350 intervals, respectively.

5 Within these magnetosheath intervals, we search for jets as described in Plaschke et al. (2013). The main criterion is based on the dynamic pressure in the anti-sunward, i.e., x -direction in geocentric solar ecliptic (GSE) coordinates: $P_{\text{dyn},x} = \rho V_x^2$. Here ρ is the ion (proton) mass density and V_x the velocity in the x -direction. $P_{\text{dyn},x}$ – measured by MMS – shall surpass half the pristine solar wind value, as determined from OMNI solar wind data. A jet interval is then defined by $P_{\text{dyn},x}$ exceeding one
10 pre-jet and post-jet intervals. All pre-jet, jet, and post-jet intervals shall be within one magnetosheath interval as defined above.

The times of maximum ratio of dynamic pressures $P_{\text{dyn},x}$ (magnetosheath over solar wind) are denoted as t_0 . We require V_x to be negative within jet intervals and surpass half of its value at t_0 within both pre- and post-jet intervals, as specified in Plaschke et al. (2013). Applying all those criteria, we obtain a data set of 9757 jets, where MMS 1, 2, 3, and 4 contribute
15 are likely to be seen by the other three spacecraft as well.

Similar to Plaschke and Hietala (2018), we introduce normalized times $t_n = -2 \dots 2$: $t_n = -2$ corresponds to the start of the pre-jet interval, $t_n = -1$ is the start of the jet interval, $t_n = 0$ equals t_0 , i.e., the time of maximum dynamic pressure ratio in the jet core, $t_n = 1$ denotes the end of the jet interval, and $t_n = 2$ would be the end of the post-jet interval. Normalized times are defined for all 9757 jets. Note that normalized times $t_n = -2 \dots 2$ correspond with times $0 \dots 4$ in Plaschke and Hietala (2018).

20 Figure 2 shows one of these jets, exemplarily, observed by MMS 1 on 24 December 2016. As can be seen in Figure 2c, the ion density clearly exceeded twice the corresponding solar wind values. Figure 2d shows the ion omni-directional energy flux density, indicating MMS 1 to be immersed in thermalized magnetosheath plasma. Therein, the spacecraft observed a clear increase in GSE V_x (Figure 2b), corresponding with a large increase in $P_{\text{dyn},x}$ (Figure 2e) over the threshold of half the solar wind dynamic pressure. The vertical lines in the figure indicate the normalized times $t_n = -2$ to 2, at 05:12:52, 05:13:52,
25 05:14:29, 05:15:23, and 05:16:23 UT, respectively. We can use these normalized times to perform superposed epoch analyses, based on pre-jet, jet, and post-jet data: Therefore, the respective time intervals are compressed/expanded to become equal between integer t_n .

Note that time intervals between $t_n = -2$ and -1 , and between $t_n = 1$ and 2 are 1 minute long by definition. The median lengths of time intervals between $t_n = -1$ and 0, and between $t_n = 0$ and 1 are 20s and 19s, respectively, with associated
30 standard deviations of 38s and 44s. Hence, in “real” time, the jet interval length can vary significantly, while typically being one third as long as the pre and post-jet intervals combined (see also Plaschke et al., 2013).

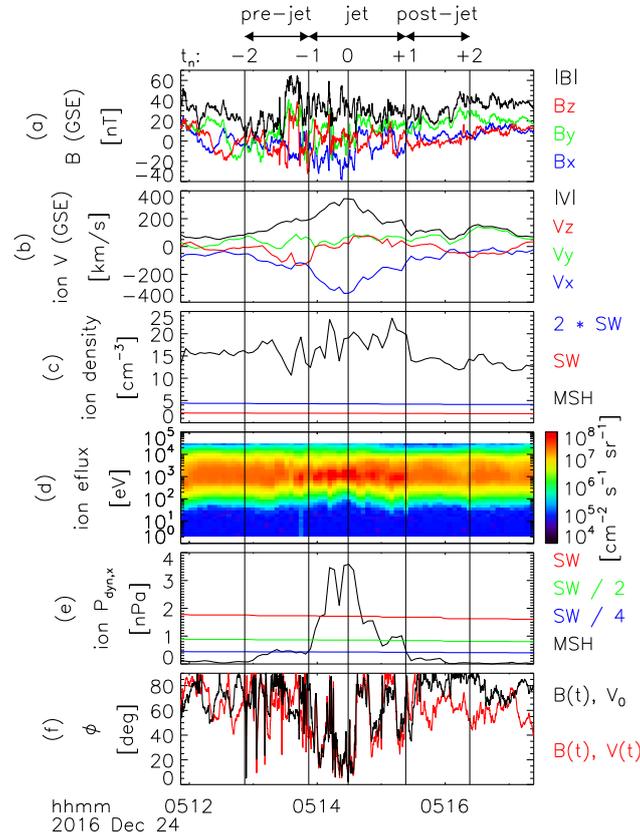

Figure 2. Jet example: MMS 1 magnetosheath and OMNI solar wind data of 24 December 2016. From top to bottom: (a) magnetic field \mathbf{B} in GSE, (b) ion velocity \mathbf{V} in GSE, (c) ion density in the magnetosheath in black and (twice) the ion density in the solar wind in red (blue), (d) magnetosheath ion energy flux density, (e) $P_{\text{dyn},x}$ in the magnetosheath in black and in the solar wind in red (half and one quarter thereof in green and blue), and (f) angles $\phi_{\mathbf{B},\mathbf{V}_0}$ in black and $\phi_{\mathbf{B},\mathbf{V}}$ in red based on magnetosheath observations. Vertical lines show normalized times $t_n = -2$ to 2 .

3 Results

The primary objective of this paper is to show whether (or not) the magnetic field aligns with the flow velocity on jet passage, as suggested by simulation results presented in Karimabadi et al. (2014) and case study observations by Plaschke et al. (2017). This can be answered by a superposed epoch analysis of the angle $\phi_{\mathbf{B},\mathbf{V}}$ (see Figure 1b) between magnetic field \mathbf{B} and ion velocity \mathbf{V} vectors. The result is shown in red in Figure 3 (see also Figure 2f, red line, for a contributing example). The solid line shows median values and the dashed lines illustrate the upper and lower quartiles.

Let's focus first on the edges of the jet interval. Before and after that interval, in the pre- and post-jet intervals, the angle $\phi_{\mathbf{B},\mathbf{V}}$ is approximately 60° and constant. At $t_n = -1$, a slight increase in the median and lower quartile of $\phi_{\mathbf{B},\mathbf{V}}$ can be seen. This corresponds to the increase in dynamic pressure $P_{\text{dyn},x}$ over one quarter of the solar wind value. At $t_n = 1$, the end of the

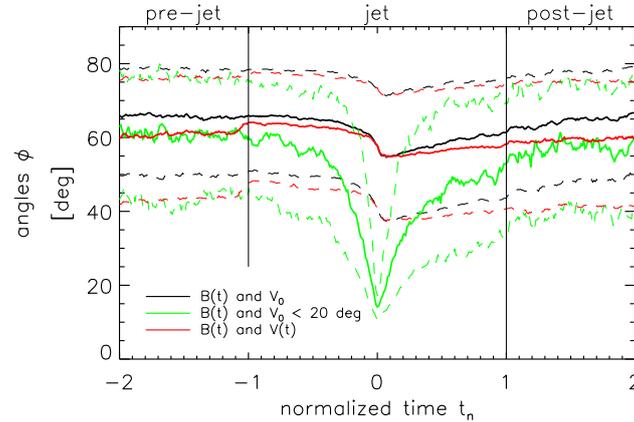

Figure 3. Superposed epoch analyses of the angles $\phi_{B,V}$ in red, ϕ_{B,V_0} in black, and ϕ_{B,V_0} of those jets where that angle is limited to 20° at $t_n = 0$ in green. Solid lines show median values, dashed lines show upper and lower quartile values.

jet interval, no significant feature in $\phi_{B,V}$ can be discerned. Instead, at that time, $\phi_{B,V}$ is gradually recovering from a decrease that sharply happens at $t_n = 0$.

The normalized time $t_n = 0$ (or t_0) is of special importance, as it marks the time of maximum dynamic pressure in the jet, the jet core. Decreases in $\phi_{B,V}$ at that time show that, generally, there is “some” alignment of B and V happening inside jets.

5 However, in the superposed epoch analysis, this effect is limited to approximately 10° .

Angles ϕ_{B,V_0} can also be computed using the velocity vector at that specific time: $V_0 = V(t_0)$. Results of a corresponding superposed epoch analysis are shown in black in Figure 3 (see also Figure 2f, black line, for a contributing example). In this case, the median ϕ_{B,V_0} shows no variation at $t_n = -1$. The decrease at $t_n = 0$ is a bit deeper, and the overall value of ϕ_{B,V_0} within the pre- and post-jet intervals is slightly higher, approximately at 65° .

10 The limited alignment effect apparent at $t_n = 0$ raises the question whether the considered effect is significant in any of the jets. Therefore, we select those jets where $\phi_{B,V_0} < 20^\circ$ at $t_n = 0$. This holds for 449 jets, i.e., for 4.6% of the jet data set. Note that the example jet shown in Figure 2 belongs to this group. The corresponding superposed epoch analysis of ϕ_{B,V_0} based only on these jets is shown in green in Figure 3. Apparently, a major alignment of B and V does happen sometimes, although only in a small minority of cases.

15 This effect may depend on the upstream solar wind or jet intrinsic conditions. As reported in Plaschke et al. (2013), the jet occurrence in the subsolar magnetosheath is heavily dependent on the IMF cone angle. The decrease in ϕ_{B,V_0} at t_0 , however, is independent from this quantity, as can be seen in Figure 4. Just the overall ϕ_{B,V_0} levels change slightly with the IMF cone angle, B and V being a few degrees more aligned, in general, under low IMF cone angle conditions. The same results with respect to cone angle dependence holds for the angles $\phi_{B,V}$ as a function of t_n (not shown).

20 Instead, the decrease in ϕ_{B,V_0} at t_0 is dependent on the velocity of the jets (Figure 5). The larger the velocity at t_0 is, the larger the decrease will usually be in ϕ_{B,V_0} . Figure 5 shows superposed epoch analyses of this quantity as a function of V_{0x} at t_0 .

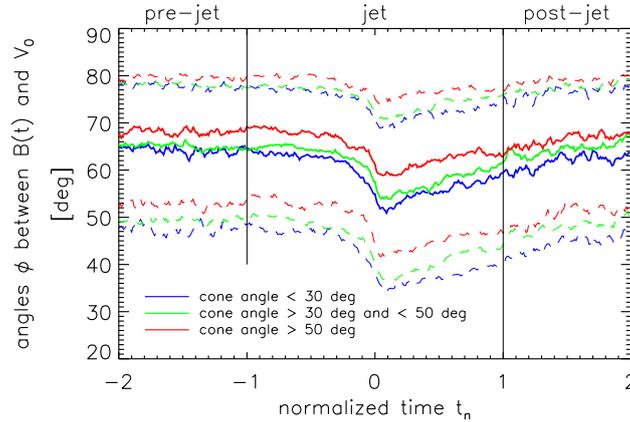

Figure 4. Superposed epoch analyses of the angle ϕ_{B,V_0} , using only jets occurring under IMF cone angles of $< 30^\circ$ (blue, 2811 contributing jets), between 30° and 50° (green, 4119 contributing jets), and above 50° (red, 2827 contributing jets), respectively. As in Figure 3, solid lines show median values and dashed lines show upper and lower quartiles.

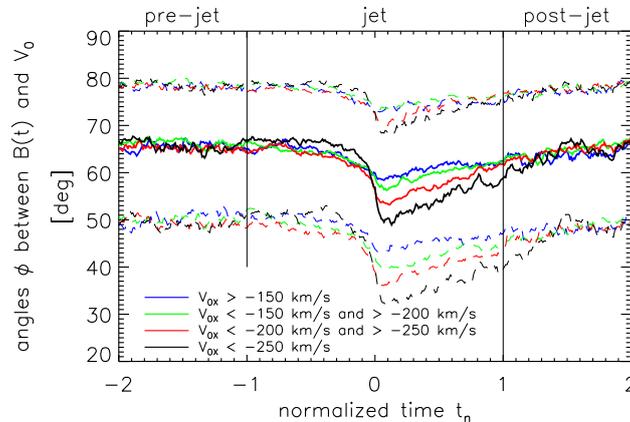

Figure 5. Superposed epoch analyses of the angle ϕ_{B,V_0} , using only jets featuring $V_{0x}(t_0) > -150$ km/s in blue (1623 contributing jets), -150 km/s $> V_{0x}(t_0) > -200$ km/s in green (3087 contributing jets), -200 km/s $> V_{0x}(t_0) > -250$ km/s in red (2699 contributing jets), and -250 km/s $> V_{0x}(t_0)$ in black (2348 contributing jets). As in Figure 3, solid lines show median values and dashed lines show upper and lower quartiles.

4 Discussion

The typical angles between magnetic field and plasma flow directions in the subsolar magnetosheath are reflected at normalized times $t_n = -2$ and 2 , at the ends of the superposed epoch analyses. As shown in Figures 3, 4, and 5, the median angles $\phi_{B,V}$ and ϕ_{B,V_0} at these times are found to be between approximately 60° and 70° . At first glance, such high values seem remarkable, taking into account that they are also found under low IMF cone angle conditions (blue line in Figure 4). However, they may

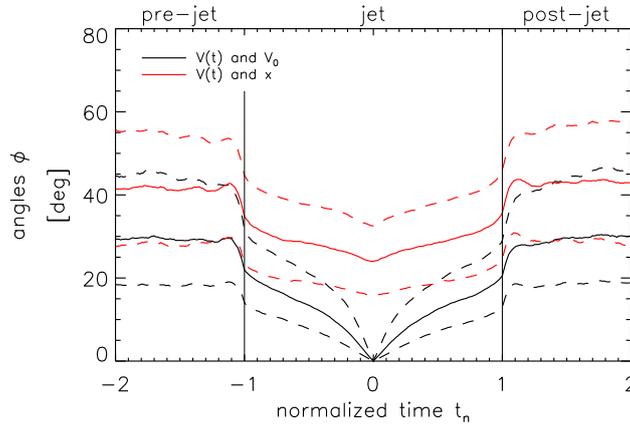

Figure 6. Superposed epoch analysis of the angle ϕ_{V,V_0} between $\mathbf{V}(t)$, the time series of velocity vectors, and \mathbf{V}_0 , the vectors at times t_0 in black. In red, the superposed epoch analysis of ϕ_{V,e_x} is shown, where e_x is the unit vector in GSE x -direction.

be explained at least to some extent by typical draping of the IMF in the magnetosheath. The median angle $\phi_{B,V}$ of all magnetosheath observations by the MMS spacecraft selected for this study is 59.2° .

The first jet-induced deviations in $\phi_{B,V}$ and ϕ_{B,V_0} are seen at $t_n = -1$. At this time, the median angle $\phi_{B,V}$ increases slightly, while ϕ_{B,V_0} does not change. As \mathbf{V}_0 stays constant, the change necessarily has to come from a change in \mathbf{V} at $t_n = -1$. This change is reflected in Figure 6, which shows superposed epoch analyses of the angles between $\mathbf{V}(t)$ with \mathbf{V}_0 and e_x in black and red, respectively. Here, e_x is the unit vector in GSE x -direction, along the Earth-Sun-line.

As can be seen in the figure, between $t_n = -1$ and 1 the jet-related plasma deflection takes places, with jets propagating more in anti-sunward direction than the ambient magnetosheath plasma. This feature is typical for jets and has been reported, e.g., by Karlsson et al. (2012) and Archer and Horbury (2013); in this study, as in Plaschke et al. (2013), it is also used to identify jets in the first place. Apparently, the flow deflection does not affect the magnetic field direction, so that ϕ_{B,V_0} stays constant at $t_n = -1$. After that time, \mathbf{V} gradually approaches \mathbf{V}_0 , as reflected in Figure 6 (see black line). Consequently, angles $\phi_{B,V}$ and ϕ_{B,V_0} behave rather similar close to $t_n = 0$. This can also be seen in Figure 2f, showing black and red lines closely aligned at $t_n = 0$ but deviating more strongly before $t_n = -1$ and, in particular, after $t_n = 1$.

In light of the decreases of ϕ_{B,V_0} at $t_n = 0$, we can confirm that jets modify magnetic fields in the magnetosheath, tending to align them with their direction of propagation. This alignment happens sharply at $t_n = 0$, i.e., at the cores of the jets that feature the fastest plasma (see Plaschke and Hietala, 2018). However, it is also clear from the statistics presented in this paper, that the alignment effect is generally small - much smaller than seen in simulations by Karimabadi et al. (2014). The reason for this discrepancy might be the restrictions imposed on plasma motion and magnetic fields in their simulations, as they were 2-dimensional (2D) and not 3D.

In general, median ϕ_{B,V_0} angles decrease by approximately 10° . Even the statistics including only the fastest jets only exhibit a decrease in median ϕ_{B,V_0} by less than 20° . The fact that faster jets lead to a stronger alignment of \mathbf{B} and \mathbf{V} is, however, not surprising as the velocity difference between jet and ambient plasmas should be responsible for the change in

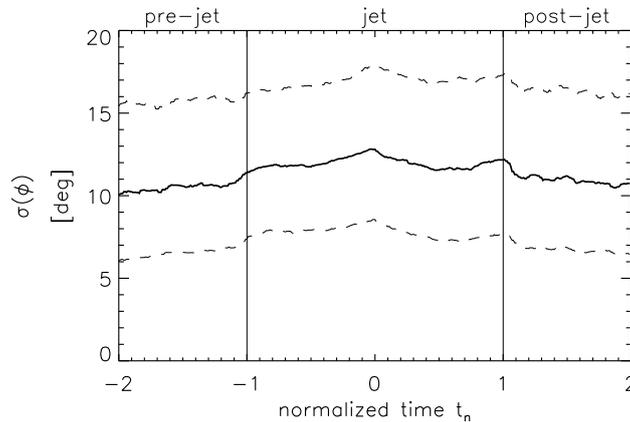

Figure 7. Superposed epoch analysis of the standard deviations of angles $\phi_{B,V}$ within 10s-wide time intervals, centered around respective normalized times. Solid line depicts median, dashed lines upper and lower quartiles.

magnetic field direction (see Figure 1a). As jets plough through slower plasma, they should drag the frozen-in magnetic field with them, straightening it at and after their passage (Plaschke et al., 2017). This picture is also in agreement with the gradual recovery of ϕ_{B,V_0} after the passage of the jet core, starting at $t_n = 0$ and extending beyond $t_n = 1$.

It shall be noted that all the results presented here pertain to average changes in B in V , emerging from superposed epoch analyses of thousands of jets. Individual jets can and will look very different. As shown in Figure 3 in green, there are jets (< 5%) featuring quite small $\phi_{B,V_0} < 20^\circ$ at t_0 . The example jet shown in Figure 2 is one of them. As can be seen in the bottom panel of Figure 2, ϕ_{B,V_0} changes a lot over the passage of this particular jet, which is not special in this respect. Within its jet interval, between $t_n = -1$ and $t_n = 1$, ϕ_{B,V_0} values close to 0° and 90° are reached in rapid succession.

To quantify this variability statistically, we compute standard deviations σ of $\phi_{B,V}$ within 10s-wide sliding time intervals for every jet. The corresponding superposed epoch analysis of $\sigma(\phi)$ is presented in Figure 7. Variability on the order of 10° seems to be typical. The median variability slightly increases within jet intervals to about 13° at $t_n = 0$. This increase is also suggested by the example displayed in Figure 2. Note that the variability in $\phi_{B,V}$ is of the same order as the typical alignment at t_0 , quantitatively supporting the observation that the alignment is hard to discern in individual events.

5 Conclusions

The purpose of this paper is to ascertain whether the high-speed motion of magnetosheath jets through slower ambient plasma leads to an alignment of magnetic and velocity fields, as predicted by simulations (Karimabadi et al., 2014) and case study observations (Plaschke et al., 2017). To address this question, we have performed superposed epoch analyses of the angles $\phi_{B,V}$ and ϕ_{B,V_0} as a function of normalized times t_n , based on MMS jet observations in the subsolar magnetosheath. These are our main results:

- In agreement with expectations, jets generally do modify the magnetic field on their passage, aligning it more with their velocity. This alignment takes place at the core of the jets, at t_0 , and it is stronger for faster jets. Recovery to usual angles ϕ occurs gradually within the trailing part of the jets.
 - In disagreement with simulations by (Karimabadi et al., 2014), this alignment is relatively small. Typically, the angles ϕ change only by about 10° . The reason for this discrepancy might be the restrictions imposed on plasma motion and magnetic fields in the simulations, as they are 2D and not 3D.
 - Time series of ϕ of individual jets look very different to the superposed epoch analysis results: Large fluctuations in ϕ on sub-jet time scales are very common. This variability is somewhat larger within jets than outside, masking the decrease in ϕ at times t_0 of individual jets.
- 10 *Data availability.* The FGM and FPI data used in this paper are stored at the MMS Science Data Center (<https://lasp.colorado.edu/mms/sdc/>) and are publicly available. The OMNI solar wind data are publicly available from the NASA Space Physics Data Facility at the Goddard Space Flight Center (https://omniweb.gsfc.nasa.gov/ow_min.html).

Author contributions. FP conceived the study and MJ did a significant part of the data analysis work. HH and LV helped with the discussion and interpretation of the results.
